

Dijkstra's Pseudocode (high-level)

1. Find start and end of your graph

2. Have a min queue ready to use

3. Initialize the weight of the vertices to ∞ . Then, initialize the weight of the start to 0.

4. While the priority queue is not empty

> Get the smallest item (top item in heap) and store it in variable (x)

> To help it run faster, mark it as visited so you don't have to worry about it later.

- Why we can do this: The way a vertex comes out of a queue is with the shortest path as it's weight, as long as there are no negative weights

relax

> Visit the neighbors and see if their weight is greater than the new weight of (current vertex + edge)
If it is, update the neighbor's weight and mark with a breadcrumb so you can trace back later

5. Once queue is empty, each vertex will have a shortest path
